Abstract

Assuming that the observed deficit of solar neutrinos is due to the interaction of their transition magnetic moment with the solar magnetic field we derive the predictions for the forthcoming Borexino experiment. Three different model magnetic field profiles which give very good global fits of the currently available solar neutrino data are used. The expected signal at Borexino is significantly lower than those predicted by the LMA, LOW and VO neutrino oscillation solutions of the solar neutrino problem. It is similar to that of the SMA oscillation solution which, however, is strongly disfavoured by the Super-Kamiokande data on day and night spectra and zenith angle distribution of the events. Thus, the neutrino magnetic moment solution of the solar neutrino problem can be unambiguously distinguished from the currently favoured oscillation solutions at Borexino.

1 Introduction

If lepton flavour is not conserved, neutrinos must have flavour-off-diagonal (transition) magnetic moments, which applies to both Dirac and Majorana neutrinos. Under a transverse magnetic field, such magnetic moments will cause a simultaneous rotation of neutrino spin and flavour, spin-flavour precession [1, 2]. This precession can be resonantly enhanced in matter [3, 4, 5], very much similarly to the resonance amplification of neutrino oscillations, the MSW effect [6].

The resonance spin-flavour precession (RSFP) of solar neutrinos due to the interaction of their transition magnetic moments with the solar magnetic field can account for the observed deficit of solar neutrinos. The conversion mechanism is neutrino energy dependent, which is a necessary feature to fit the data. RSFP requires relatively large values of the neutrino transition magnetic moment, $\mu_\nu \sim 10^{-11} \mu_B$ for peak values of the solar magnetic field $B_0 \sim 100$ kG. Although such values of μ_ν are not experimentally excluded, they are hard to achieve in the simplest extensions of the standard electroweak model. Still, the RSFP mechanism yields an excellent fit of all currently available solar neutrino data (see, e.g., [7 – 13] for recent analyses), typically even somewhat better than does the large mixing angle (LMA) oscillation solution, which is the best one among the oscillation solutions. In any case, in pursuit of the solution of the solar neutrino problem it is very important to test all non-standard hypotheses, and neutrino magnetic moment seems to be the most plausible alternative to neutrino oscillations.

As non-vanishing neutrino transition magnetic moments imply lepton flavour violation, they must be accompanied by the usual lepton flavour mixing. Thus RSFP should in general coexist with neutrino oscillations. It is quite possible, however, that the flavour mixing in the solar neutrino sector is too small to be of any relevance to the solar neutrino problem. This is our assumption in the present paper, i.e. we neglect neutrino oscillations and consider pure RSFP transitions. Small flavor mixing in the solar sector does not contradict the large mixing in the atmospheric neutrino sector – the corresponding mixing angles are independent parameters. In this connection, one can recall that the lepton mixing angle θ_{13} probed in short-baseline reactor neutrino experiments is known to be small or vanishing [14] even though the “atmospheric” mixing angle θ_{23} is large [15].

Unfortunately, the RSFP solution of the solar neutrino problem is difficult to establish experimentally. Except for predicting reduced detection rates of solar neutrinos (which the oscillation solutions also predict), it has mostly negative signatures: No time variations beyond the usual $1/R^2$ variation due to the eccentricity of the Earth’s orbit (assuming that the strongest component of the solar magnetic field does not vary with time)¹; no day-night effect; no significant distortions of the solar neutrino spectrum in Super-Kamiokande and SNO experiments. One might therefore think that the RSFP solution of the solar neutrino problem can only be established if all the oscillation solutions are experimentally ruled out.

¹There is a caveat here which we shall discuss in Section 3 – strictly speaking, this is only true when the solar magnetic field is spherically symmetric.

Such a “negative” confirmation would hardly satisfy anyone.

In the present paper we show that in fact this is not the case: the RSFP predictions for the Borexino experiment are very different from those of neutrino oscillations, and different solutions of the solar neutrino problem can therefore be unambiguously distinguished experimentally.

2 Predictions for Borexino

The Borexino experiment at Gran Sasso [16], due to start data taking this year, will detect solar neutrinos through the elastic νe scattering. Extremely high radiopurity of the liquid scintillator used and very low background will allow the detection of record low energy recoil electrons. In the electron kinetic energy window $T_e = 250 - 800$ keV which will be used in the experiment, the major contribution to the signal (78%) is expected from a monochromatic line of ${}^7\text{Be}$ neutrinos with the energy 863 keV. The next important contributions are from ${}^{15}\text{O}$, ${}^{13}\text{N}$ and *pep* neutrinos (10%, 7.2% and 3.6% respectively), and the predicted detection rate is 55 events/day [16], all according to the BP00 standard solar model [17, 18] and assuming that neutrinos are “standard” (i.e. have no mass, mixing and/or magnetic moment). A lower signal is expected if neutrinos undergo RSFP or oscillations.

We have calculated the expected event rates at Borexino in the case of the RSFP mechanism assuming that neutrinos have Majorana-like transition magnetic moments μ_ν which cause the transitions $\nu_{eL} \rightarrow \bar{\nu}_{\mu R}$ or $\nu_{eL} \rightarrow \bar{\nu}_{\tau R}$ in the solar magnetic field. We have restricted ourselves to the Majorana neutrino case because it gives much better a fit of the solar neutrino data than the Dirac case does. The transition probability depends crucially on the shape and strength of the solar magnetic field which are essentially unknown; one therefore is forced to use various model magnetic field profiles. In our previous work [8, 9, 13] we have studied eight different magnetic field profiles. All of them except three gave either very poor or marginal global fits of the data of the Homestake, Gallex/GNO, SAGE, Super-Kamiokande and SNO solar neutrino experiments [19], while the above mentioned three profiles gave very good global fits of the data (see Table 1 below). In the present paper we use these three profiles to predict the signal at Borexino. We believe that they provide a representative sample of the profiles that are capable of fitting the solar neutrino data. The calculation and fitting procedures are described in detail in our previous papers [8], [9] and [13]. Profiles I and II used here are profiles 1 and 6 of ref. [8], whereas profile III of the present paper is profile 4 of ref. [13]. The value of μ_ν was fixed at $10^{-11}\mu_B$; since only the product of the magnetic moment and magnetic field enters in the neutrino evolution equation, our results apply to any other value of μ_ν provided that the magnetic field is rescaled accordingly. We use the “BP00 + new ${}^8\text{B}$ ” standard solar model, i.e. the solar matter distribution and all the neutrino fluxes except the ${}^8\text{B}$ one from [17], whereas for the ${}^8\text{B}$ flux we use the new value [18, 20] which is based on a recent precise measurement of the cross section of the reaction ${}^7\text{Be}(p, \gamma){}^8\text{B}$ [21]. It is about 17% higher than the previously used value. We have also calculated the Borexino event rates with the “old” ${}^8\text{B}$ flux and

found no significant changes in the results.

Table I: Reduced rates (event rates assuming RSFP divided by the standard solar model predictions with no flavour changes allowed) for Gallex/GNO + SAGE, Homestake, Super-Kamiokande and SNO experiments which correspond to the global best fits for the three magnetic field profiles used, along with the corresponding experimental data. The values of χ^2_{min} correspond to 39 d.o.f. See the text for more details.

Profile	R_{Ga}	R_{Cl}	R_{SK}	R_{SNO}	Δm^2 (eV ²)	B_0 (kG)	χ^2_{min}
I	0.59	0.30	0.41	0.35	$7.65 \cdot 10^{-9}$	45	37.8
II	0.58	0.30	0.39	0.33	$1.60 \cdot 10^{-8}$	113	36.1
III	0.58	0.30	0.40	0.33	$1.48 \cdot 10^{-8}$	101	35.5
Exp.	$0.57 \pm .039$	$0.30 \pm .026$	$0.39 \pm .014$	$0.30 \pm .025$			

In Table 1 we give, for the three magnetic field profiles used, the calculated reduced detection rates R_i (rates assuming RSFP divided by those for “standard” neutrinos) for SAGE+Gallex/GNO (Ga), Homestake (Cl), Super-Kamiokande (SK) and SNO experiments. The indicated rates correspond to the best global fits of the data (all rates plus day and night spectra at Super-Kamiokande). For each profile we show the corresponding best-fit values of Δm^2 , peak magnetic field strength parameter B_0 , and χ^2_{min} (39 d.o.f.). In the last line we give the experimental detection rates normalized to the “BP00 + new 8B ” standard solar model.

As can be seen from the table, all three profiles yield very good global fits of the data. Profile I produces slightly worse a fit than those given by profiles II and III, mainly because it predicts too high a SNO rate. For the “old” values of the 8B neutrino flux, the allowed regions of parameters at 95% CL and 99% CL for profiles I and II and for profile III were given in fig. 1 and fig. 2 of ref. [13], respectively. If one uses instead the new 8B flux, the allowed regions are slightly shifted (by about 5%) towards higher values of the magnetic field strengths. For illustration, in fig. 1 we show the 95% CL allowed regions for profile III for both old and new 8B fluxes.

In Table 2 predictions are given for the reduction factors of the individual contributions of various solar neutrino fluxes to the Borexino event rate (the contributions to the event rate assuming RSFP divided by those for “standard” neutrinos). The results are given, for each of the three magnetic field profiles, for the values of Δm^2 and B_0 that produced the best global fits of the currently available data (see Table 1).

Finally, in Table III we present the predicted values of the reduced event rates for Borexino R_{Bor} . We give there the values of R_{Bor} corresponding to the best-fit values of Δm^2 and B_0 as well as the minimum and maximum values of R_{Bor} corresponding to the 95% CL and 99% CL allowed ranges of Δm^2 and B_0 .

Figure 1: Allowed regions of Δm^2 (in eV^2) and B_0 (in G) for profile III at 95% CL. Solid curve – new ^8B flux, dashed curve – old ^8B flux. The best fit points are shown by dots.

Table II: Columns 2 to 8 – reduction factors of the individual contributions of different solar neutrino fluxes to the Borexino event rate (the contributions to the event rate assuming RSFP divided by those for “standard” neutrinos). Last column – reduction factors for the total event rate. The values of Δm^2 and B_0 correspond to the best fits of the present data (see Table 1).

Profile	pp	pep	^7Be	^{15}O	^{13}N	^8B	hep	total
I	0.71	0.18	0.29	0.26	0.32	0.44	0.47	0.28
II	0.64	0.24	0.42	0.35	0.43	0.42	0.44	0.41
III	0.62	0.30	0.35	0.35	0.39	0.44	0.46	0.35

3 Discussion

The main goal of this work was to investigate whether RSFP can be distinguished from the oscillation solutions of the solar neutrino problem at Borexino. There are four main types of oscillation solutions of the solar neutrino problem, depending on the allowed values of the leptonic mixing angle θ and neutrino mass squared difference Δm^2 : Large mixing angle (LMA), small mixing angle (SMA) and low- Δm^2 (LOW) MSW solutions, and also vacuum oscillation (VO) solution (for recent discussions see, e.g., [22, 23, 20, 24, 25, 12]). The LMA, LOW and VO solutions all predict the average suppression of the event rate at Borexino by 35 – 40%, whereas in the case of the SMA solution a suppression by about a factor of five is expected.

The main feature of the RSFP mechanism which can be exploited in order to distinguish it experimentally from neutrino oscillations is the peculiar shape of the energy dependence of the survival probability of solar neutrinos: At high energies it resembles the ν_e survival probability of the LMA oscillation solution, whereas at low energies it is similar to that of

Table III: Predicted reduced event rates (rates assuming RSFP divided by the standard solar model predictions with no flavour changes allowed) for Borexino R_{Bor} .

Profile	b.f.	min (95% CL)	max (95% CL)	min (99% CL)	max (99% CL)
I	0.28	0.21	0.50	0.21	0.57
II	0.41	0.29	0.57	0.28	0.62
III	0.35	0.31	0.52	0.30	0.57

the SMA solution. A mismatch in the results of the experiments sensitive to the high-energy and low-energy parts of the solar neutrino spectrum would therefore be an indication for RSFP.

As can be seen from Table III, the RSFP mechanism predicts the suppression of the event rate at Borexino by about a factor of three. The maximum allowed at 99% CL reduced rate is 0.62; this only marginally overlaps with the minimum allowed at 3σ reduced rate in the case of the LMA solution (0.58, see Table 7 of ref. [20]). Thus, the predictions of the RSFP and LMA solutions are more than 5σ away from each other and the probability of mistaking one for another is very low.

The minimum allowed at 3σ values of the reduced rate at Borexino in the case of LOW and VO solutions, 0.54 and 0.53 respectively [20], are slightly lower than that for the LMA solution, so that there is a larger overlap with the 99% CL prediction of the RSFP. However, in these cases, too, one can easily discriminate between RSFP and the oscillation solutions. Indeed, in the case of the LOW solution one expects a sizeable (up to 40%) day-night event rate difference at Borexino, while VO should lead to large seasonal variations beyond the usual $1/R^2$ dependence. No such effects are predicted by RSFP.

Our predictions for the reduced event rate at Borexino in the case of RSFP are slightly higher than those of the SMA oscillation solution, although there is a significant overlap between the predicted rates in these two cases. It should be noted, however, that the SMA solution is strongly disfavoured by the data on day and night spectra and zenith angle distributions of recoil electrons at Super-Kamiokande [26]. We therefore conclude that Borexino will allow a clear discrimination between RSFP and currently favoured oscillation solutions of the solar neutrino problem. It should be noted that new dedicated low-energy solar neutrino experiments, which are widely discussed now [27], should have a similar or even stronger discriminative power ².

The RSFP mechanism may also lead to some specific effects, absent in the case of neutrino oscillation solutions. If the solar magnetic field is not axially symmetric, the rotation of the Sun can lead to a time variation of the signal with the period equal to the solar rotation period (about 28 Earth's days). Seasonal variations of the signal can also occur due to the inclination (by about 7°) of the solar equatorial plane to the Earth's orbit, provided that the solar magnetic field depends on the polar angle Θ . This effect depends

²We thank M. Nakahata for pointing this out to us.

on the three-dimensional structure of the solar magnetic field. For the model profile of ref. [10], the transverse component $B_{\perp} \propto \sin \Theta$; since for solar neutrinos reaching the Earth $\Theta = 90^{\circ} \pm 7^{\circ}$, one finds seasonal variations of less than $\pm 1.5\%$ for charged-current signals. In the case of neutrino detection through νe scattering (Super-Kamiokande, SNO and Borexino), these variations are further diluted by the neutral-current contribution to the event rates. Thus, the seasonal variations of this kind are probably too small to be observable.

Another possible signature of RSFP is an observable flux of $\bar{\nu}_e$ from the Sun if neutrinos, in addition to transition magnetic moments, have a sizeable flavour mixing ($\theta \gtrsim 0.1$) [28]. The flux of solar $\bar{\nu}_e$'s at the level of 1% of the ν_e flux can, in principle, be detected at Borexino and SNO. However, these signatures depend on additional assumptions about θ and the structure of the solar magnetic field, whereas our predictions for the Borexino detection rate are essentially model independent. The only possible model dependence is contained in the choice of the solar magnetic field profile, and this freedom is severely constrained by the requirement of fitting the available solar neutrino data. As a result, the predictions for the Borexino event rate, though somewhat different for different profiles (see Table III), all fall below those for the LMA, LOW and VO solutions.

In conclusion, we have shown that the Borexino experiment will be able to unambiguously distinguish RSFP from the currently favoured oscillation solutions of the solar neutrino problem.
